4 1 *Introduction*

5 Seagrasses are ecologically valuable components of aquatic systems that serve a structural  
6 and functional role maintaining aquatic habitat. These ‘ecosystem engineers’ can affect aquatic  
7 systems through multiple feedback mechanisms with other ecosystem components (Jones et al.  
8 1994, Koch 2001). For example, seagrass beds create habitat for juvenile fish and crabs by  
9 reducing wave action and stabilizing sediment (Williams and Heck 2001, Hughes et al. 2009).  
10 Seagrasses also respond to changes in water clarity through direct physiological linkages with  
11 light availability. Seagrass communities in highly productive aquatic systems may be light-limited  
12 as increased nutrient loading may contribute to reductions in water clarity through increased algal  
13 concentrations (Duarte 1995). Empirical relationships between nutrient loading, water clarity,  
14 light requirements, and the maximum depth of seagrass colonization have been identified (Duarte  
15 1991, Kenworthy and Fonseca 1996, Choice et al. 2014) and are often been used to characterize  
16 light regimes sufficient to maintain aquatic habitat through increased seagrass coverage (Steward  
17 et al. 2005). Conversely, seagrass depth limits have formed the basis of quantitative criteria for  
18 nutrient load targets for the maintenance of water quality (Janicki and Wade 1996). Seagrasses  
19 are integrative of system-wide conditions over time in relation to changes in nutrient regimes  
20 (Duarte 1995) and are often preferred biological endpoints to describe ecosystem response to  
21 perturbations relative to more variable taxa (e.g., phytoplankton). Quantifying the relationship of  
22 seagrasses with water clarity is a viable means of understanding ecological characteristics of  
23 aquatic systems with potential insights into resilience and stability of system response to  
24 disturbance (Greve and Krause-Jensen 2005).

25 A variety of techniques have been developed for estimating seagrass depth limits as a

26 basis for understanding water quality dynamics and developing a more robust description of  
27 aquatic habitat. Such efforts have been useful for site-specific approaches where the analysis  
28 needs are driven by a particular management or research context (e.g., [Iverson and Bittaker 1986](#),  
29 [Hale et al. 2004](#)). However, a lack of standardization among methods has prevented broad-scale  
30 comparisons between regions and has even contributed to discrepancies between measures of  
31 depth limits based on the chosen technique. For example, seagrass depth limits based on in situ  
32 techniques can vary with the sampling device ([Spears et al. 2009](#)). Estimates of seagrass depth  
33 limits can also be obtained from geospatial data that describe aerial coverage of seagrass and  
34 bathymetric depth distribution. Despite the availability of such data, flexible techniques for  
35 estimating seagrass depth of colonization have not been extensively developed nor have  
36 standardized techniques been implemented across broad areas. A common technique is the  
37 quantification of depth limits within a predefined management units as a relevant spatial context.  
38 For example, [Steward et al. \(2005\)](#) describe a segmentation scheme for the Indian River Lagoon  
39 on the east coast of Florida that was used to assign seagrass depth limits to 19 distinct geospatial  
40 units. Although useful within a limited scope, substantial variation in growth patterns and water  
41 quality characteristics at different spatial scales may prevent more detailed analyses leading to  
42 limited descriptions of aquatic habitat. Methods for estimating seagrass depth limits should be  
43 reproducible for broad-scale comparisons, while also maintaining flexibility for site-specific  
44 estimates depending on research or management objectives. Such techniques have the potential to  
45 facilitate broad-scale comparisons between regions given the spatial coverage and annual  
46 availability of many data sources.

47 A useful application comparing depth limit measures and water clarity is the estimation of  
48 light requirements to evaluate ecologically relevant characteristics of seagrass communities.

49 Although growth of submersed aquatic plants is generally most limited by light availability  
50 (Barko et al. 1982, Hall et al. 1990, Dennison et al. 1993), variation in the maximum depth of  
51 growth for a given level of water clarity is not uncommon based on differences in light  
52 requirements (Dennison et al. 1993, Choice et al. 2014). In general, seagrasses with low light  
53 requirements are expected to grow deeper than seagrasses with high requirements as related to  
54 species or regional differences in community attributes. Duarte (1991) indicate that minimum  
55 light requirements for seagrasses are on average 11% of surface irradiance, although values may  
56 range from less than 5% to greater than 30% (Dennison et al. 1993). Further, significant variation  
57 in light requirements in seagrasses along the Gulf Coast of peninsular Florida were attributed to  
58 morphological and physiological differences between species and adaptations to regional light  
59 regimes (Choice et al. 2014). Spatial heterogeneity in light requirements is, therefore, a useful  
60 diagnostic tool for evaluating additional factors that may limit seagrass growth. Potentially novel  
61 insights into ecological characteristics of aquatic systems can be obtained by evaluating light  
62 requirements. For example, high light requirements estimated from maximum depth of  
63 colonization and water clarity may suggest seagrass growth is limited by high biomass of  
64 epiphytic algal growth that reduces light availability on the leaf surface (Kemp et al. 2004).  
65 Accordingly, quantitative and flexible methods for estimating seagrass depth limits and light  
66 requirements have the potential to greatly improve ecological descriptions of aquatic habitat.

67 This article describes a method for estimating seagrass depth of colonization using  
68 information-rich datasets to create a spatially explicit and flexible measure. In particular, an  
69 empirical algorithm is described that estimates seagrass depth limits from aerial coverage maps  
70 and bathymetric data using an *a priori* defined area of influence. These estimates are combined  
71 with measures of water clarity to provide a spatially robust characterization of light requirements

72 to better understand factors that limit seagrass growth. The specific objectives are to 1) describe  
73 the method for estimating seagrass depth limits within a relevant spatial context, 2) apply the  
74 technique to four distinct regions of Florida to illustrate improved clarity of description for  
75 seagrass growth patterns, and 3) develop a spatial description of depth limits, water clarity, and  
76 light requirements for the case studies. Overall, these methods are expected to inform the  
77 description of seagrass growth patterns to develop a more ecologically relevant characterization of  
78 aquatic habitat. The method is applied to data from Florida although the technique is easily  
79 transferable to other regions with comparable data.

## 80 **2 Methods**

81 Estimates of seagrass depth of colonization ( $Z_c$ ) that are derived from relatively broad [acro:doc]  
82 spatial aggregations may not fully describe relevant variation depending on the question of  
83 interest. Fig. 1a shows variation in seagrass distribution for a management segment (thick  
84 polygon) in the Big Bend region of Florida. The maximum depth colonization, shown as a red  
85 contour line, is based on a segment-wide average of all seagrasses within the polygon. Although  
86 such an estimate is unbiased, substantial variation in seagrass growth patterns at smaller spatial  
87 scales is not adequately described.  $Z_c$  is greatly over-estimated at the outflow of the Steinhatchee  
88 River (northeast portion of the segment) where high concentrations of dissolved organic matter  
89 reduce water clarity and naturally limit seagrass growth. This example suggests that it may be  
90 useful to have improved spatial resolution in estimates of  $Z_c$ , particularly when site-specific  
91 characteristics may require a more detailed description of seagrass growth patterns. The following  
92 is a summary of data sources, methods and rationale for improving spatial resolution in seagrass  
93  $Z_c$  estimates, and evaluation of the approach including relationships with water clarity. Data and

94 methods described in Hagy, In review are used as a foundation for developing the approach.

95 **2.1 Data sources**

96 **2.1.1 Study sites**

97 Four locations in Florida were chosen for the analysis: Choctawhatchee Bay (Panhandle),

98 Big Bend region (northeast Gulf of Mexico), Tampa Bay (central Gulf Coast), and Indian River

99 Lagoon (east coast) (Table 1 and Fig. 2). These locations represent different geographic regions in

100 the state, in addition to having available data and observed gradients in water clarity that

101 contribute to heterogeneity in seagrass growth patterns. For example, the Big Bend region was

102 chosen based on location near an outflow of the Steinhatchee River where higher concentrations

103 of dissolved organic matter are observed. Seagrasses near the outflow were observed to grow at

104 shallower depths as compared to locations far from the river source. Coastal regions and estuaries

105 in Florida are partitioned as distinct spatial units based on a segmentation scheme developed by

106 US Environmental Protection Agency (EPA) for the development of numeric nutrient criteria. {acro:EPA}

107 One segment from each geographic location was used to estimate seagrass  $Z_c$  and to evaluate

108 variation in growth patterns. The segments included portions of Choctawhatchee Bay (segment

109 303), the big bend region (820), Old Tampa Bay (902), and Indian River Lagoon (1502) (Fig. 2).

110 **2.1.2 Seagrass coverage and bathymetry** {sec:data\_}

111 Spatial data describing seagrass aerial coverage combined with co-located bathymetric

112 depth information were used to estimate  $Z_c$ . These geospatial data products are publicly

113 available in coastal regions of Florida through the US Geological Survey, Florida Department of

114 Environmental Protection, Florida Fish and Wildlife Conservation Commission, and watershed

115 management districts. Seagrass coverage maps were obtained for recent years in each of the study

116 sites described above (Table 1). Coverage maps were produced using photo-interpretations of  
117 aerial images to categorize seagrass as absent, discontinuous (patchy), or continuous. For this  
118 analysis, we considered seagrass as only present (continuous and patchy) or absent since  
119 differences between continuous and patchy coverage were often inconsistent between data  
120 sources.

121 Bathymetric depth layers for each location were obtained from the National Oceanic and  
122 Atmospheric Administration's (NOAA) National Geophysical Data Center  
123 (<http://www.ngdc.noaa.gov/>) as either Digital Elevation Models (DEMs) or raw sounding data {acro:DEM}  
124 from hydroacoustic surveys. Tampa Bay data provided by the Tampa Bay National Estuary  
125 Program are described in [Tyler et al. \(2007\)](#). Bathymetric data for the Indian River Lagoon were  
126 obtained from the St. John's Water Management District ([Coastal Planning and Engineering](#)  
127 [1997](#)). NOAA products were referenced to mean lower low water, whereas Tampa Bay data were  
128 referenced to the North American Vertical Datum of 1988 (NAVD88) and the Indian River {acro:NAV}  
129 Lagoon data were referenced to mean sea level. Depth layers were combined with seagrass  
130 coverage layers using standard union techniques for raster and vector layers in ArcMap 10.1  
131 ([Environmental Systems Research Institute 2012](#)). To reduce computation time, depth layers were  
132 first masked using a 1 km buffer of the seagrass coverage layer. Raster bathymetric layers were  
133 converted to vector point layers to combine with seagrass coverage maps, described below. All  
134 spatial data were referenced to the North American Datum of 1983 as geographic coordinates.  
135 Depth values in each seagrass layer were further adjusted from the relevant vertical reference  
136 datum to local mean sea level (MSL) using the NOAA VDatum tool (<http://vdatum.noaa.gov/>). {acro:MSL}

137 **2.1.3 Water clarity**

138 Seagrass light requirements can be estimated by evaluating spatial relationships between  
139 depth of colonization and water clarity. Secchi measurements provide a precise estimate of water  
140 clarity and have been obtained at numerous locations documented in the Florida Department of  
141 Environmental Protection's Impaired Impaired Waters Rule (IWR) database. Secchi data (as {acro:IWR})  
142 depth in meters,  $Z_{secchi}$ ) for Florida coastal waters were obtained from update 40 of the IWR  
143 database for all of Tampa Bay (2010 coverage) and the Indian River Lagoon (2009 coverage)  
144 given the spatial extent of secchi observations for the two locations relative to the Big Bend and  
145 Choctawhatchee segments. Secchi data within the previous ten years of the seagrass coverage  
146 data were evaluated to capture water quality trends from the most recent decade (i.e., 1999–2009  
147 for the Indian River Lagoon and 2000–2010 for Tampa Bay). Stations with less than five  
148 observations and observations that were flagged indicating that the value was lower than the  
149 maximum depth of the observation point were removed. Secchi data were also compared with  
150 bathymetric data to verify unflagged values were not missed by initial screening. Secchi  
151 observations that were measured at the same geographic location were averaged across all dates.  
152 This approach was preferred given that seagrass depth patterns are more representative of  
153 long-term trends in water clarity as opposed to individual secchi measures that may be highly  
154 variable (Dennison 1987, Dennison et al. 1993).

155 **2.2 Flexible estimation of seagrass depth of colonization for finite areas**

156 The general approach to estimating seagrass depth of colonization uses combined seagrass  
157 coverage maps and bathymetric depth data described above. The combined layer used for analysis  
158 was a point shapefile with attributes describing location (latitude, longitude, segment), depth (m),

159 and seagrass (present, absent). Seagrass  $Z_c$  values are estimated from these data by quantifying  
160 the proportion of points with seagrass at each observed depth. Three unique measures describing  
161 seagrass depth limits obtained from these data are minimum ( $Z_{c,min}$ ), median ( $Z_{c,med}$ ), and  
162 maximum ( $Z_{c,max}$ ) depth of colonization. Operationally, these terms describe characteristics of  
163 the seagrass coverage map with quantifiable significance.  $Z_{c,max}$  is defined as the deepest depth  
164 at which a significant coverage of mappable seagrasses occurred independent of outliers, whereas  
165  $Z_{c,med}$  is the median depth occurring at the deep water edge.  $Z_{c,min}$  is the depth at which seagrass  
166 coverage begins to decline with increasing depth and may not be statistically distinguishable from  
167 zero depth, particularly in turbid waters. Specific methods for estimating each  $Z_c$  value using  
168 spatially-resolved information are described below.

169 The spatially-resolved approach for estimating  $Z_c$  begins by choosing an explicit location  
170 in cartesian coordinates within the general boundaries of the available data. Seagrass depth data  
171 (i.e., merged bathymetric and seagrass coverage data) that are located within a set radius from the  
172 chosen location are selected for estimating seagrass  $Z_c$  values (Fig. 1). The estimate for each  
173 location is quantified from a plot of the proportion of sampled points that contain seagrass at  
174 decreasing 0.1 meter depth bins from the surface to the maximum observed depth in the sample  
175 (Fig. 3a). Although the chosen radius for selecting depth points is problem-specific, the minimum  
176 radius should be chosen to sample a sufficient number of points for estimating  $Z_c$ . In general, an  
177 appropriate radius will produce a plot that indicates a decrease in the proportion of points that are  
178 occupied by seagrass with increasing depth. If more than one location is used to estimate  $Z_c$ ,  
179 appropriate radii for each point would have minimal overlap with the seagrass depth data sampled  
180 by neighboring points.

181 A curve is fit to the sampled depth points using non-linear regression to characterize the

reduction in seagrass as a function of depth (Fig. 3b). Specifically, a decreasing logistic growth curve is used with the assumption that seagrass decline with increasing depth is monotonic and asymptotic at the minimum and maximum depths of colonization. The curve is fit by minimizing the residual sums-of-squares with the Gauss-Newton algorithm (Bates and Chambers 1992) and starting parameters estimated from the observed data that are initial approximations of the curve characteristics. The model has the following form:

$$Proportion = \frac{\alpha}{1 + e^{(\beta - Z)/\gamma}} \quad (1) \quad \{eqn:prop\}$$

where the proportion of points occupied by seagrass at each depth,  $Z$ , is defined by a logistic curve with an asymptote  $\alpha$ , a midpoint inflection  $\beta$ , and a scale parameter  $\gamma$ . Finally, a simple linear curve is fit through the inflection point ( $\beta$ ) of the logistic curve to estimate the three measures of depth of colonization (Fig. 3c). The inflection point is considered the depth at which seagrass are decreasing at a maximum rate and is used as the slope of the linear curve. The maximum depth of seagrass colonization,  $Z_{c, max}$ , is the x-axis intercept of the linear curve. The minimum depth of seagrass growth,  $Z_{c, min}$ , is the location where the linear curve intercepts the upper asymptote of the logistic growth curve. The median depth of seagrass colonization,  $Z_{c, med}$ , is the depth halfway between  $Z_{c, min}$  and  $Z_{c, max}$ .  $Z_{c, med}$  is typically the inflection point of the logistic growth curve.

Estimates for each of the three  $Z_c$  measures are obtained only if specific criteria are met. These criteria were implemented as a safety measure that ensures a sufficient amount and appropriate quality of data were sampled within the chosen radius. First, estimates were provided only if a sufficient number of seagrass depth points were present in the sampled data to estimate a

202 logistic growth curve. This criteria applies to the sample size as well as the number of points with  
203 seagrass in the sample. Second, estimates were provided only if an inflection point was present on  
204 the logistic curve within the range of the sampled depth data. This criteria applied under two  
205 scenarios where the curve was estimated but a trend was not adequately described by the sampled  
206 data. That is, estimates were unavailable if the logistic curve described only the initial decrease  
207 in points occupied as a function of depth but the observed points do not occur at depths deeper  
208 than the predicted inflection point. The opposite scenario occurred when a curve was estimated  
209 but only the deeper locations beyond the inflection point were present in the sample. Third, the  
210 estimate for  $Z_{c,min}$  was set to zero depth if the linear curve through the inflection point  
211 intercepted the asymptote at x-axis values less than zero. The estimate for  $Z_{c,med}$  was also shifted  
212 to the depth value halfway between  $Z_{c,min}$  and  $Z_{c,max}$  if  $Z_{c,min}$  was fixed at zero. Finally,  
213 estimates were considered invalid if the 95% confidence interval for  $Z_{c,max}$  included zero.  
214 Methods used to determine confidence bounds on  $Z_c$  estimates are described below.

### 215 **2.3 Estimating uncertainty in depth of colonization estimates**

216 Confidence intervals for the  $Z_c$  values were estimated using a Monte Carlo simulation  
217 approach that considered the variance and covariance between the model parameters ([Hilborn and](#)  
218 [Mangel 1997](#)). For simplicity, we assume that the variability associated with parameter estimates  
219 is the dominant source of uncertainty. A 95% confidence interval for each  $Z_c$  estimate was  
220 constructed by repeated sampling of a multivariate normal distribution followed by prediction of  
221 the proportion of points occupied by seagrass as in eq. (1). The sampling distribution assumes:

$$x \sim N(\mu, \Sigma) \quad (2)$$

222 where  $x$  is a predictor variable used in eq. (1) (depth) that follows a multivariate normal  
223 distribution with mean  $\mu$ , and variance-covariance matrix  $\Sigma$ . The mean values are set at the depth  
224 value corresponding to the inflection point on the logistic curve and the predicted model  
225 parameters (i.e.,  $\alpha$ ,  $\beta$ , and  $\gamma$ ), whereas  $\Sigma$  is the variance-covariance matrix of the model  
226 parameters. A large number of samples ( $n = 10000$ ) were drawn from the distribution to  
227 characterize the uncertainty of the depth value at the inflection point. The 2.5<sup>th</sup> and 97.5<sup>th</sup> quantile  
228 values of the sample were considered bounds on the 95% confidence interval.

229 The uncertainty associated with the  $Z_c$  estimates was based on the upper and lower limits  
230 of the estimated inflection point on the logistic growth curve. This approach was used because  
231 uncertainty in the inflection point is directly related to uncertainty in each of the  $Z_c$  estimates that  
232 are based on the linear curve fit through the inflection point. Specifically, linear curves were fit  
233 through the upper and lower estimates of the depth value at the inflection point to identify upper  
234 and lower limits for the estimates of  $Z_{c,min}$ ,  $Z_{c,med}$ , and  $Z_{c,max}$ . These values were compared  
235 with the initial estimates from the linear curve that was fit through the inflection point on the  
236 predicted logistic curve (i.e., Fig. 3c). This approach provided an indication of uncertainty for  
237 individual estimates for the chosen radius. Uncertainty estimates were obtained for each  $Z_c$   
238 estimate for the grids in each segment.

239 The algorithm for estimating  $Z_c$  was implemented custom-made and pre-existing  
240 functions in program R. Nonlinear least squares models were based on the `nls` and `SSlogis`  
241 functions that used a self-starting logistic growth model (Bates and Chambers 1992, R  
242 Development Core Team 2014). Multivariate normal distributions used to evaluate uncertainty  
243 were simulated using functions in the MASS package (Venables and Ripley 2002). Geospatial  
244 data were imported and processed using functions in the `rgeos` and `sp` packages (Bivand et al.

245 2008, Bivand and Rundel 2014).

## 246 2.4 Evaluation of spatial heterogeneity of seagrass depth limits

247 Spatially-resolved estimates for seagrass  $Z_c$  were obtained for each of the four coastal  
248 segments described above. Segment-wide estimates obtained using all data were used as a basis  
249 of comparison such that departures from these values at smaller scales were evidence of spatial  
250 heterogeneity in seagrass growth patterns and improved clarity of description in depth estimates.

251 A sampling grid of locations for estimating each of the three depth values in Fig. 3 was created  
252 for each segment. The grid was masked by the segment boundaries, whereas seagrass depth  
253 points used to estimate  $Z_c$  extended beyond the segment boundaries to allow sampling by grid  
254 points that occurred near the edge of the segment. Initial spacing between sample points was  
255 chosen arbitrarily as 0.02 decimal degrees, which is approximately 2 km at 30 degrees N latitude.  
256 The sampling radius around each sampling location in the grid was also chosen as 0.02 decimal  
257 degrees to allow for complete coverage of seagrass within the segment while also minimizing  
258 redundancy of information described by each location. In other words, radii were chosen such  
259 that the seagrass depth points sampled by each grid location were only partially overlapped by  
260 those sampled by neighboring points.

## 261 2.5 Developing a spatially coherent relationship of water clarity with depth 262 of colonization

263 The relationship between the quantified seagrass depth limits and secchi measurements  
264 were explored by estimating light requirements from standard attenuation equations. The  
265 traditional Lambert-Beer equation describes the exponential decrease of light availability with  
266 depth:

$$I_z = I_O \cdot \exp(-K_Z \cdot Z) \quad (3) \quad \{\text{eqn:lambert}\}$$

such that the irradiance of incident light at depth  $Z$  ( $I_Z$ ) can be estimated from the irradiance at the surface ( $I_O$ ) and a light extinction coefficient ( $K_Z$ ). Light requirements of seagrass at a specific location can be estimated by rearranging eq. (3):

$$\% \text{ light} = \exp(-K_Z \cdot Z_{c, max}) \quad (4) \quad \{\text{eqn:perc}\}$$

where the percent light requirements of seagrass at  $Z_{c, max}$  are empirically related to light extinction. A conversion factor is often used to estimate the light extinction coefficient from secchi depth  $Z_{secchi}$ , such that  $c = K_Z \cdot Z_{secchi}$ , where  $c$  has been estimated as 1.7 (Poole and Atkins 1929, Idso and Gilbert 1974). Thus,  $K_Z$  can be replaced with the conversion factor and  $Z_{secchi}$ :

$$\% \text{ light} = \exp\left(-\left(\frac{1.7}{Z_{secchi}}\right) \cdot Z_{c, max}\right) \quad (5) \quad \{\text{eqn:cperc}\}$$

Variation in seagrass light requirements by location can be considered biologically meaningful.

The geographic coordinates for each secchi measurement in all of Tampa Bay and the Indian River Lagoon were used as locations for estimating  $Z_{c, max}$ . These estimates were compared with the averaged secchi estimates for the prior ten years to identify seagrass light requirements at each location (i.e., 2000–2010 for Tampa Bay, 1999–2009 for Indian River Lagoon). However, the relationship may vary depending on the specific radius around each sample point for estimating  $Z_{c, max}$ . A sufficiently large radius was chosen that was approximately an order of magnitude larger than that used for the individual segments given that  $Z_{c, max}$  estimates were to be compared for whole bays rather than within segments. The estimated maximum depth values and light requirements of each point were plotted by location to evaluate

285 spatial variation in seagrass growth as a function of light-limitation.

## 286 **3 Results**

### 287 **3.1 Segment characteristics and seagrass depth estimates**

288        Each of the four segments varied by several key characteristics that potentially explain  
289        within-segment variation of seagrass growth patterns (Table 1). Mean surface area was 191.2  
290        square kilometers, with area decreasing for the Big Bend (271.4 km), Indian River Lagoon (NA  
291        km), Old Tampa Bay (205.5 km), and Choctawhatchee Bay (59.4 km) segments. Seagrass  
292        coverage as a percentage of total surface area varied considerably by segment. Seagrasses covered  
293        a majority of the surface area for the Big Bend segment (74.8 %), whereas coverage was much  
294        less for Indian River Lagoon (NA %), Old Tampa Bay (11.9 %), and Choctawhatchee Bay (5.9  
295        %). Visual examination of the seagrass coverage maps for the respective year of each segment  
296        suggested that seagrasses were not uniformly distributed (Fig. 2). Seagrasses in the  
297        Choctawhatchee Bay segments were generally sparse with the exception of a large patch located  
298        to the west of the inlet connection with the Gulf of Mexico. Seagrasses in the Big Bend segment  
299        were located throughout the segment with noticeable declines near the outflow of the  
300        Steinhatchee River, whereas seagrasses in Old Tampa Bay and the Indian River Lagoon segment  
301        were generally confined to shallow areas near the shore. Seagrass coverage showed a partial  
302        decline toward the northern ends of both Old Tampa Bay and the Indian River Lagoon segments.  
303        Mean depth was less than 5 meters for each segment, excluding Choctawhatchee Bay which was  
304        slightly deeper than the other segments on average (5.3 m). Maximum depths were considerably  
305        deeper for Choctawhatchee Bay (11.9 m) and Old Tampa Bay (10.4 m), as compared to the Big  
306        Bend (3.6 m) and Indian River Lagoon (NA m) segments. Water clarity as indicated by average

307 secchi depths was similar between the segments (1.5 m), although Choctawhatchee Bay had a  
308 slightly higher average (2.1 m).

309 Estimates of seagrass  $Z_c$  using a segment-wide approach that did not consider spatially  
310 explicit locations indicated that seagrasses generally did not grow deeper than three meters in any  
311 of the segments (Table 2). Maximum and median depth of colonization were deepest for the Big  
312 Bend segment (3.7 and 2.5 m, respectively) and shallowest for Old Tampa Bay (1.1 and 0.9 m),  
313 whereas the minimum depth of colonization was deepest for Choctawhatchee Bay (1.8 m) and  
314 shallowest for Old Tampa Bay (0.6 m). Averages of all grid-based estimates for each segment  
315 were different than the segment wide estimates, which suggests potential bias associated with  
316 using a whole segment as a relevant spatial unit for estimating depth of colonization. In most  
317 cases, the averages of all grid-based estimates were less than the whole segment estimates,  
318 suggesting the latter provided an over-estimate of seagrass growth limits. For example, the  
319 average of all grid estimates for  $Z_{c, max}$  in the Big Bend region suggested seagrasses grew to  
320 approximately 2 m, which was 1.6 m less than the whole segment estimate. This reduction is  
321 likely related to improved resolution of seagrass depth limits near the outflow of the Steinhatchee  
322 river. Although reductions were not as severe for the average grid estimates for the remaining  
323 segments, considerable within-segment variation was observed depending on grid location. For  
324 example, the deepest estimate for  $Z_{c, min}$  (2 m) in the Indian River Lagoon exceeded the average  
325 of all grid locations for  $Z_{c, max}$  (1.7 m).  $Z_{c, min}$  also had minimum values of zero meters for the  
326 Big Bend and Old Tampa Bay segments, suggesting that seagrasses declined continuously from the  
327 surface for several locations.

328 Visual interpretations of seagrass depth estimates using the grid-based approach provided  
329 further information on the distribution of seagrasses in each segment (Fig. 4). Spatial

330 heterogeneity in depth limits was particularly apparent for the Big Bend and Indian River Lagoon  
331 segments. As expected, depth estimates indicated that seagrasses grew deeper at locations far  
332 from the outflow of the Steinhatchee River in the Big Bend segment. Similarly, seagrasses were  
333 limited to shallower depths at the north end of the Indian River Lagoon segment near the Merrit  
334 Island National Wildlife Refuge. Seagrasses were estimated to grow at maximum depths up to 2.1  
335 m on the eastern portion of the Indian River Lagoon segment. Spatial heterogeneity was less  
336 distinct for the remaining segments. Seagrasses in Old Tampa Bay grew deeper in the northeast  
337 portion of the segment and declined to shallower depths near the inflow at the northern edge.  
338 Spatial variation in the Choctawhatchee Bay segment was not apparent, although the maximum  
339  $Z_c$  estimate was observed in the northeast portion of the segment.  $Z_c$  values were not available for  
340 all grid locations given the limitations imposed in the estimation method.  $Z_c$  could not be  
341 estimated in locations where seagrasses were sparse or absent, nor where seagrasses were present  
342 but the sampled points did not exhibit a sufficient decline with depth. The latter scenario was  
343 most common in Old Tampa Bay and Choctawhatchee Bay where seagrasses were unevenly  
344 distributed or confined to shallow areas near the shore. The former scenario was most common in  
345 the Big Bend segment where seagrasses were abundant but locations near the shore were  
346 inestimable given that seagrasses did not decline appreciably within the depths that were sampled.

347 Uncertainty for estimates of  $Z_{c, max}$  indicated that confidence intervals were generally  
348 acceptable (i.e., greater than zero), although the ability to discriminate between the three depth  
349 estimates varied by segment (Fig. 5 and Table 3). Mean uncertainty for all estimates in each  
350 segment measured as the width of a 95% confidence interval was 0.2 m. Greater uncertainty was  
351 observed for Choctawhatchee Bay (mean width of all confidence intervals was 0.7 m) and Old  
352 Tampa Bay (0.4 m), compared to the Big Bend (0.1 m) and Indian River Lagoon (0.1 m)

353 segments. The largest confidence interval for each segment was 1 m for Old Tampa Bay, 2.5 m for  
354 Choctawhatchee Bay, 0.4 m for the Big Bend, and 0.3 m for the Indian River Lagoon segments.  
355 However, most confidence intervals for the remaining grid locations were much smaller than the  
356 maximum in each segment. A comparison of overlapping confidence intervals for  $Z_{c,min}$ ,  $Z_{c,med}$ ,  
357 and  $Z_{c,max}$  at each grid location indicated that not every measure was unique. Specifically, only  
358 12.5% of grid points in Choctawhatchee Bay and 38.9% in Old Tampa Bay had significantly  
359 different estimates, whereas 84% of grid points in the Indian River Lagoon and 94.1% of grid  
360 points in the Big Bend segments had estimates that were significantly different. By contrast, all  
361 grid estimates in Choctawhatchee Bay and Indian River Lagoon had  $Z_{c,max}$  estimates that were  
362 significantly greater than zero, whereas all but 10% of grid points in Old Tampa Bay and 5.6% of  
363 grid points in the Big Bend segment had  $Z_{c,max}$  estimates significantly greater than zero.

### 364 **3.2 Evaluation of seagrass light requirements**

365 Estimates of seagrass depth limits and corresponding light requirements for all segments  
366 of Tampa Bay and the Indian River Lagoon indicated substantial variation, both between and  
367 within the different bays (Table 4 and Figs. 6 and 7). Seagrass  $Z_c$  estimates were obtained for 61  
368 locations in Tampa Bay and 50 locations in the Indian River Lagoon where secchi observations  
369 were available in the Florida IWR database. Mean secchi depth for all recorded observations was  
370 1.9 m ( $n = 61$ ) for Tampa Bay and 1 m ( $n = 50$ ) for Indian River Lagoon. Mean light  
371 requirements were significantly different between the bays (two-sided t-test,  $t = 8.5$ ,  $df = 109$ ,  
372  $p < 0.001$ ) with a mean requirement of 23% for Tampa Bay and 10.6% for Indian River Lagoon.  
373 Within each bay, light requirements were significantly different between segments (ANOVA,  $F =$   
374 5.6,  $df = 3, 57$ ,  $p = 0.00$  for Tampa Bay,  $F = 5.2$ ,  $df = 7, 42$ ,  $p = 0.000$  for Indian River

<sup>375</sup> Lagoon). However, post-hoc evaluation of all pair-wise comparisons of mean light requirements  
<sup>376</sup> indicated that significant differences were only observed between a few segments within each  
<sup>377</sup> bay. Significant differences in Tampa Bay were observed between Old Tampa Bay and  
<sup>378</sup> Hillsborough Bay (Tukey multiple comparisons,  $p = 0.032$ ). Significant differences in the Indian  
<sup>379</sup> River Lagoon were observed between the Upper Indian River Lagoon and Banana River ( $p =$   
<sup>380</sup> 0.915), the Upper Indian River Lagoon and Lower Indian River Lagoon ( $p = 0.140$ ), and Upper  
<sup>381</sup> Indian River Lagoon and Lower St. Lucie ( $p = 0.103$ ) segments. In general, spatial variation of  
<sup>382</sup> light requirements in Tampa Bay suggested that seagrasses were less light-limited (i.e., lower  
<sup>383</sup> percent light requirements at  $Z_{c,max}$ ) in Hillsborough Bay and western areas of Lower Tampa Bay  
<sup>384</sup> near the Gulf of Mexico (Fig. 6). Seagrassess in the Indian River Lagoon were generally less  
<sup>385</sup> light-limited towards the south and in the Banana River segment (Fig. 7).

Table 1: Characteristics of coastal segments used to evaluate seagrass depth of colonization estimates (see Fig. 2 for spatial distribution). Year is the date of the seagrass coverage and bathymetric data. Latitude and longitude are the geographic centers of each segment. Area and depth values are meters and square kilometers, respectively. Secchi measurements (m) were obtained from the Florida Department of Environmental Protection’s Impaired Waters Rule (IWR) database, update number 40. Secchi mean and standard errors are based on all observations within the ten years preceding each seagrass survey.<sup>tab:seg\_summ</sup>

(b) Logistic growth curve fit through points

(c) Depth estimates

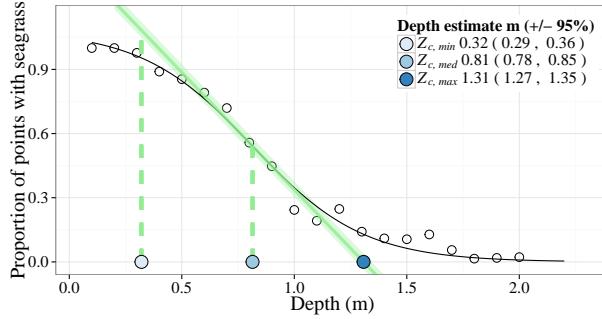

Fig. 3: Methods for estimating seagrass depth of colonization using sampled seagrass depth points around a single location. Fig. 3a is the proportion of points with seagrass by depth using depth points within the buffer of the test point in Fig. 1. Fig. 3b adds a decreasing logistic growth curve fit through the points. Fig. 3c shows three depth estimates based on a linear curve fit through the inflection point of logistic growth curve.

{fig:est\_e}

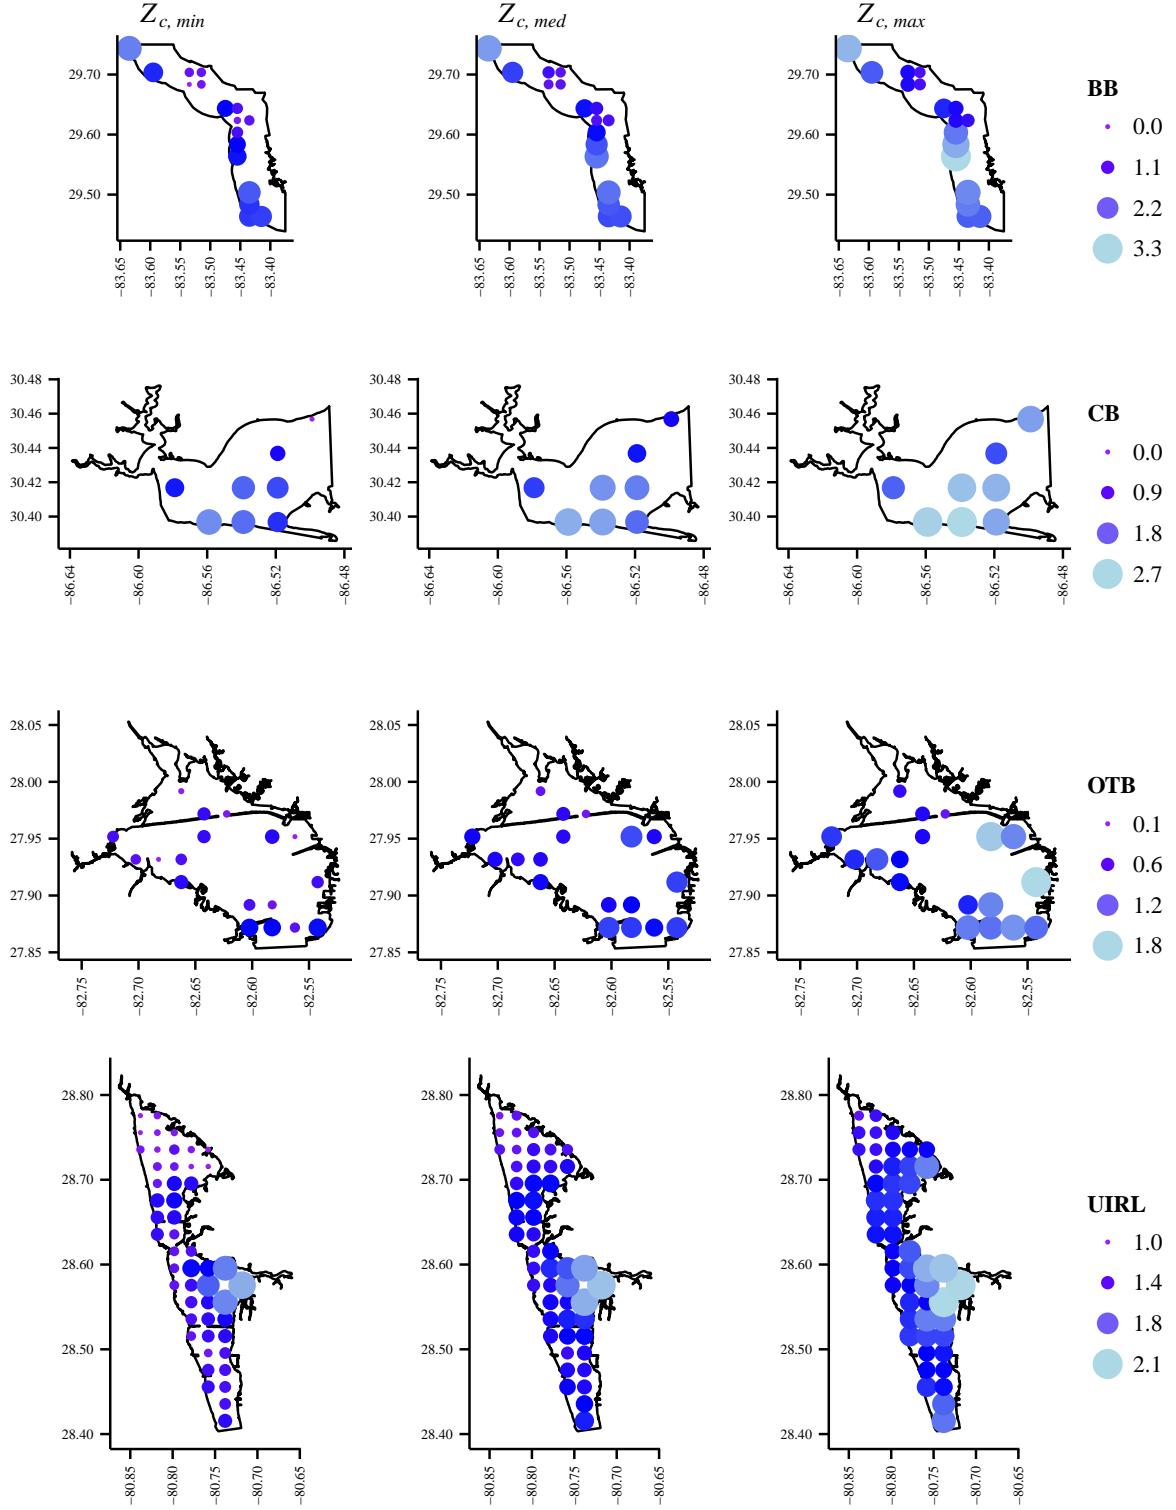

Fig. 4: Spatially-resolved estimates of seagrass depth limits (m) for four coastal segments of Florida. Estimates include minimum ( $Z_{c, \text{min}}$ ), median ( $Z_{c, \text{med}}$ ), and maximum depth of colonization ( $Z_{c, \text{max}}$ ). Estimates are assigned to grid locations for each segment, where grid spacing was fixed at 0.02 decimal degrees. Radii for sampling seagrass bathymetric data around each grid location were fixed at 0.06 decimal degrees. BB: Big Bend, CB: Choctawhatchee Bay, OTB: Old Tampa Bay, UIRL: Upper Indian R. Lagoon.

{fig:all\_e}

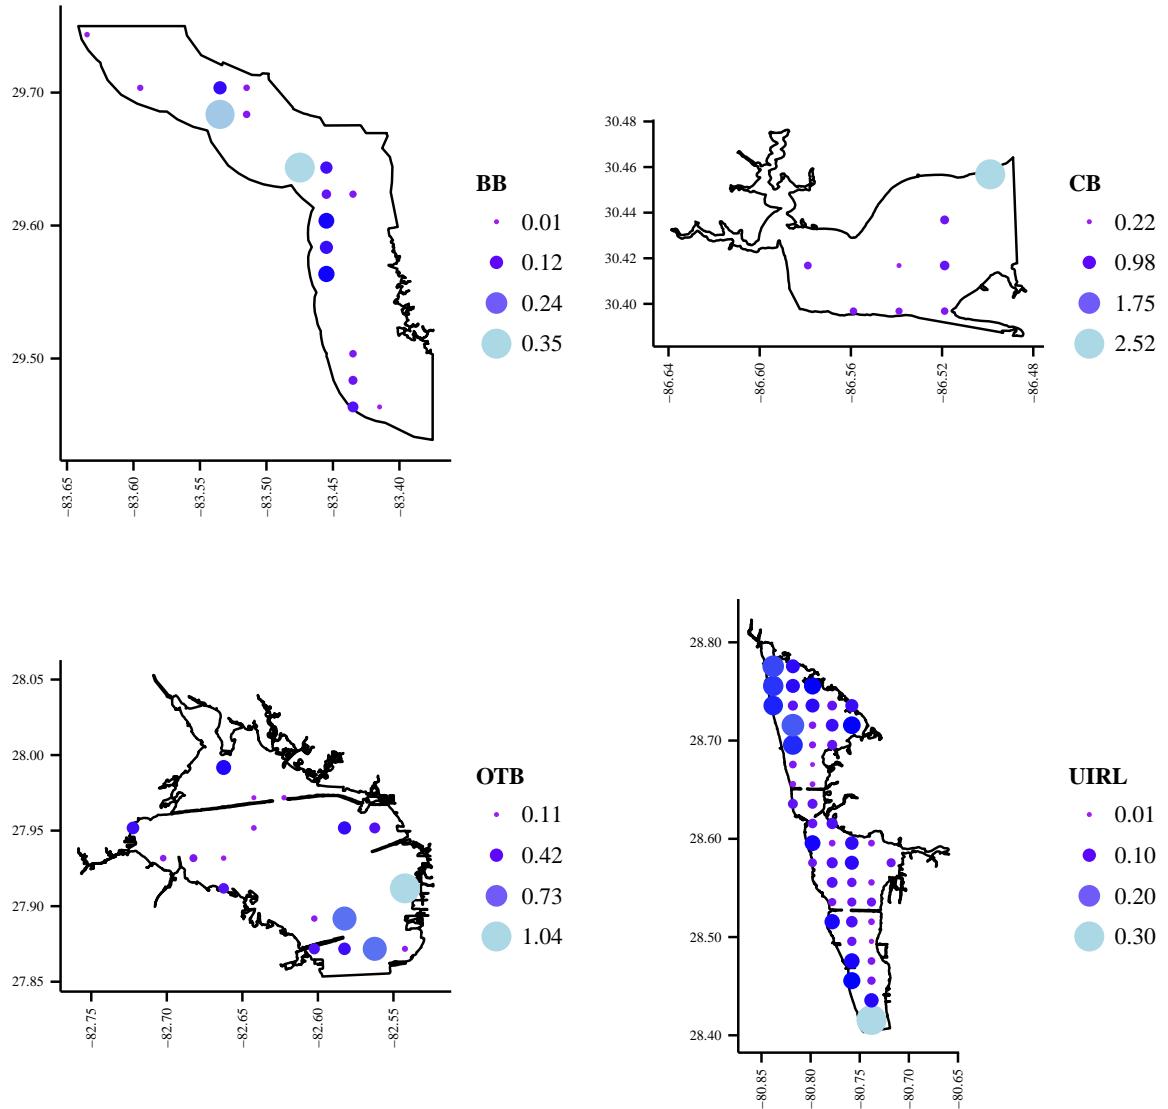

Fig. 5: Size of confidence intervals (m) for depth of colonization estimates in Fig. 4. Points are colored and sized based on the difference between the upper and lower bounds of a 95% confidence interval for all three  $Z_c$  estimates ( $Z_{c,min}$ ,  $Z_{c,med}$ ,  $Z_{c,max}$ ). Bounds were obtained using Monte Carlo simulations to estimate uncertainty associated with the inflection point of the estimated logistic curve (Fig. 3) for each sample. BB: Big Bend, CB: Choctawhatchee Bay, OTB: Old Tampa Bay, UIRL: Upper Indian R. Lagoon.

{fig:all\_s}

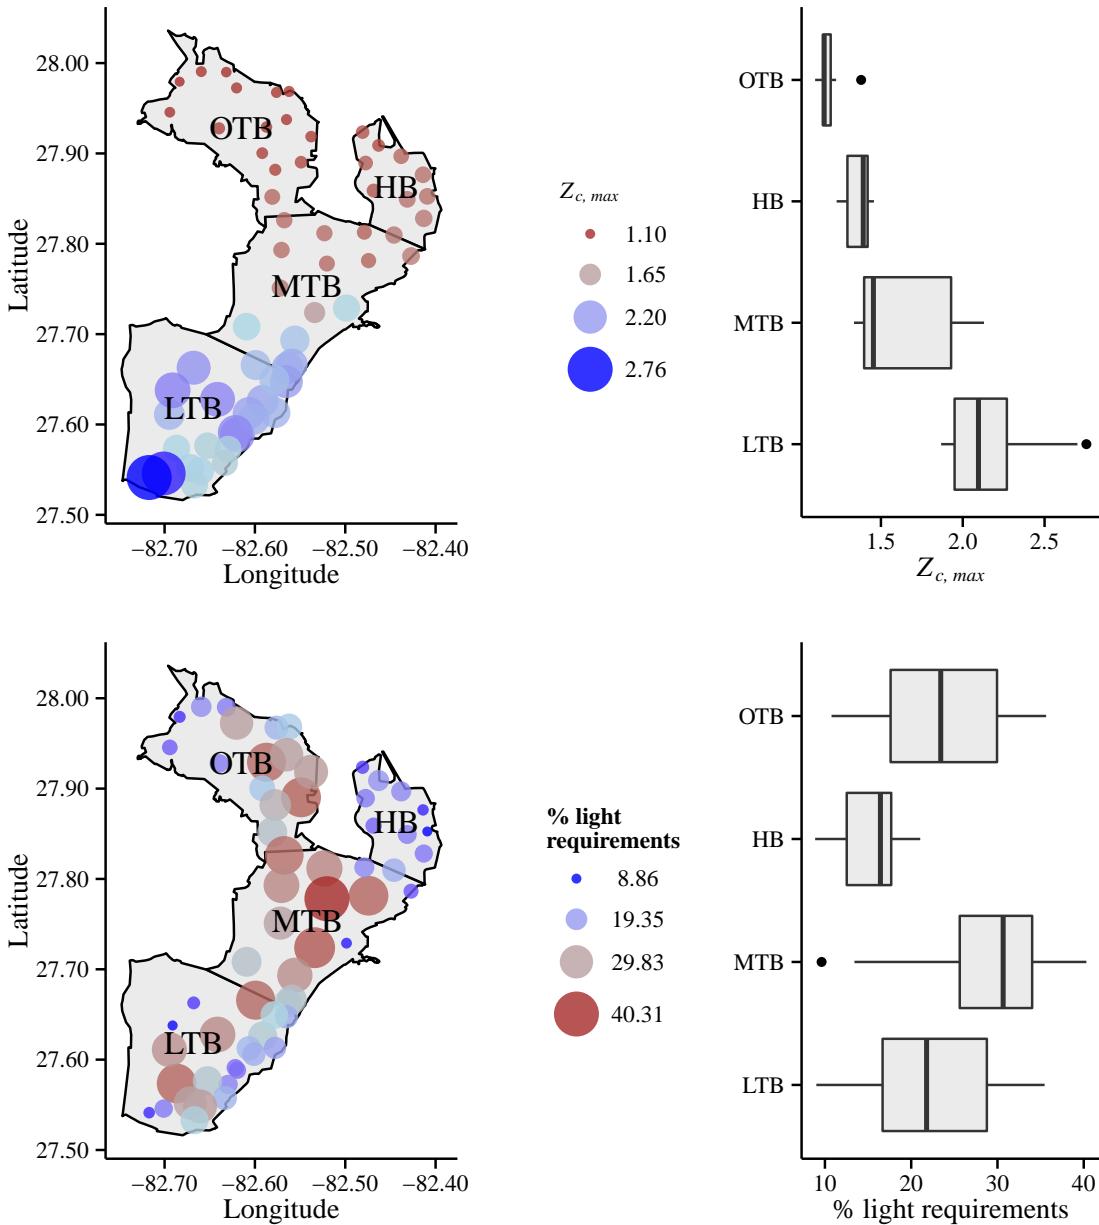

Fig. 6: Estimated maximum depths of seagrass colonization and light requirements for multiple locations in Tampa Bay, Florida. Map locations are georeferenced observations of water clarity from secchi measurements in the Florida Impaired Waters Rule database, update 40. Estimates are also summarized by bay segment as boxplots where the dimensions are the 25<sup>th</sup> percentile, median, and 75<sup>th</sup> percentile. Whiskers extend beyond the boxes as 1.5 multiplied by the interquartile range. Light requirements are based on averaged secchi values within ten years of the seagrass coverage data and estimated maximum depth of colonization using a radius of 0.02 decimal degrees for each secchi location to sample seagrass depth points. HB: Hillsborough Bay, LTB: Lower Tampa Bay, MTB: Middle Tampa Bay, OTB: Old Tampa Bay.
